Superior destabilization effects of LiBH₄ with the addition of nano-sized nickel ferrite NiFe₂O₄

Jun Zhang, a Ping Li, *a Qi Wan, b Fugiang Zhai, c Alex A. Volinsky and Xuanhui Qua

The introduction of a secondary compound, known as destabilization, is an effective way to improve the desorption performance of LiBH₄. In this paper the effects of nano-sized nickel ferrite (NiFe₂O₄) on the hydrogen storage properties of LiBH₄, processed by high energy ball milling, are studied. Non-isothermal desorption results show that the onset and predominant dehydrogenation temperature of LiBH₄ + 9 mol% NiFe₂O₄ is 89 °C and 190 °C, respectively. This is 226 °C and 260 °C lower than the fusion and decomposition temperature of LiBH₄, respectively. Moreover, over 10 wt% hydrogen can be obtained by 500 °C heating, compared with 2.4 wt% for the as-received LiBH₄. Additionally, over 5 wt% hydrogen can be released at 300 °C within 20 minutes of isothermal desorption. From the X-ray diffraction results and the small area electron diffraction analysis, Fe₃O₄, NiB and Fe₃B, *in situ* formed between the reaction of LiBH₄ and NiFe₂O₄, and act to give actual destabilization effects.

1. Introduction

Hydrogen, as an eco-friendly and renewable energy carrier, is considered to be an alternative fuel for powering future vehicles. 1-3 Since vehicles need compact, affordable and safe H2 containment to satisfy commercial needs, conventional hydrogen storage methods, including high-pressure tanks or condensation into liquid,4 need to be modified to meet the increasingly demanding requirements. Therefore, this motivation has inspired scientists to research innovative hydrogen storage systems. Solid hydrogen storage materials have recently emerged as a new solution.3 Some complex hydrides, like alanates, amides and borohydrides, have recently attracted considerable attention for potential hydrogen storage due to high hydrogen reserve mass and light weight.⁵ In particular, lithium borohydrides (LiBH₄), possessing a high volumetric and gravimetric hydrogen density of 121 kg H₂ m⁻³ and 18.5 wt%, ^{2,6} is highly desirable for on-board H2 storage in fuel cell vehicles. However, unacceptable hydrogen desorption temperature⁶ (starts at around 400 °C and releases only half the hydrogen below 600 °C) and hash re-hydrogenation conditions⁷ (at 600 °C under 350 bar H₂) inhibit its practical applications. Over the past decades, researchers around the world have attempted numerous methods, including reacting with metal hydrides,⁸⁻¹¹ restricting its particle size¹²⁻¹⁴ and doping with metals¹⁵⁻¹⁸ *etc.*, to improve the hydrogen storage properties of LiBH₄. Even though tremendous advances have been achieved, none of these approaches can simultaneously fulfill all of the revised US DOE's 2010 criteria¹⁹ to date.

Oxides have been commonly reported to be an effective method to enhance the hydrogen storage behaviors of LiBH₄. The early application of oxides can be dated back to 2003, when Züttel et al. firstly mixed LiBH4 with SiO2 to lower the onset desorption temperature to 200 °C, nearly a reduction of 200 °C compared with the pure LiBH₄, accompanied with 2.3 wt% H_{2.6} Then in 2008, Yu et al. found that TiO2 can significantly enhance the hydrogen properties of LiBH4 (the initial dehydrogenation temperature at 150 °C and the majority liberation of H₂ below 220 °C), with the charge transfer between Ti and B. They also suggested that other metal oxides with variable oxidation states should also play a similar role.20 After that in 2009, Yu et al. systematically investigated a series of oxides to find out that the order of destabilization effect for LiBH4 was $Fe_2O_3 > V_2O_5 > Nb_2O_5 > TiO_2$. Though the improvements talked are encouraging, the primary desorption temperature is still too high. The reports discussed above, however, have given us a hint to search for some novel oxides, especially some metal oxides with both variable valent as well as larger Pauling's electronegativity.21

To the best knowledge of us, no studies have been reported on LiBH₄ doped with Ni ferrite oxide (NiFe₂O₄). Meanwhile, from Li's report,²² NiFe₂O₄ shows a remarkable improvements on LiAlH₄ with the *in situ* formed LiFeO₂ and Al–Ni compounds. Likewise, the destabilization effects of NiFe₂O₄ may also be

applicable to LiBH₄ when considering that LiBH₄ has a similar performance with LiAlH₄. Also, Zhai *et al.* points out that MnFe₂O₄ has better effect than Fe or Mn oxides alone in improving the dehydrogenation properties of LiAlH₄.²³ Due to the fact that Ni has a larger Pauling's electronegativity than Mn, we ultimately added NiFe₂O₄ nanoparticles to investigate their effects on the dehydrogenation performance of LiBH₄ prepared by high energy ball milling in this work.

2. Experimental details

LiBH $_4$ (\geq 95% pure), purchased from Acros Organics, and NiFe $_2$ O $_4$ (\geq 99.99% pure, 20 nm), synthesized by the autocombustion process (details of the synthesis process were given in the previous report²⁴), were utilized directly without any further purification. LiBH $_4$ doped with different mole ratios (3 mol%, 5 mol%, 7 mol%, 9 mol% and 11 mol%) of NiFe $_2$ O $_4$ was ball-milled under argon atmosphere by using a QM-3B high energy mill (Nanjing NanDa Instrument Plant) at a rotating speed of 1200 rpm for 30 min. Two kinds of stainless steel balls with 4 mm and 8 mm diameters were added with a ball-to-powder weight ratio of 30 : 1. Typically, 2 g mixture was sealed in the stainless steel vessel within a high purity argon atmosphere during milling. To avoid excess heating of the stainless steel vessel, there were 10 min intervals between each 5 min milling process.

The non-isothermal and isothermal desorption were measured by using the Sieverts-type pressure-compositiontemperature (P-C-T) apparatus (General Research Institute for Nonferrous Metals, China). Typically, 0.5 g sample was loaded into a stainless steel vessel and then heated from room temperature (RT) to 500 °C at a heating rate of 5 °C min⁻¹ under 0.001 MPa hydrogen pressure. It should be noted that the additional content was not taken into consideration when calculating the released hydrogen in order to make a comparison with the as-received LiBH₄. The phase structure of the samples after milling and dehydrogenation was examined by an MXP21VAHF X-ray Diffractometer (XRD with Cu Kα radiation, 40 kV, 300 mA), with the 2θ angle ranged from 10° to 90° with a scanning rate of 10° min⁻¹. The morphology and phase constitution of all samples after ball milling and desorption were observed by field-emission scanning electron microscopy (FESEM, ZEISS ULTRA55, Germany) and transmission electron microscopy (Tecnai G2 F30 S-TWIN, FEI, USA). Simultaneous differential scanning calorimetry and mass spectrometry (DSC-MS) experiments were conducted under 50 mL min⁻¹ argon flow in a NETZSCH STA 449F3 Jupiter instrument connected to a mass spectrometer (MS, Hiden Analytical HPR-20 QMS sampling system) between 50 °C and 500 °C with a heating rate of 5 °C min⁻¹. The samples were transferred to Al₂O₃ crucibles under argon atmosphere for the DSC-MS measurements. Fourier transform infrared spectroscopy (FT-IR) analysis of the samples were carried out by using Nexus 670 FT-IR spectrometer. The FT-IR spectra were recorded from 32 scans between $500~\mathrm{cm}^{-1}$ and $3000~\mathrm{cm}^{-1}$ with a spectral resolution of $4~\mathrm{cm}^{-1}$.

All samples handling were performed under strictly inert conditions (≥99.99% Ar atmosphere) in the glove box

(Mikrouna, Super-750) equipped with oxygen/humidity sensors and recirculation system to avoid oxidation and moisture. Oxygen and $\rm H_2O$ levels were kept below 0.1 ppm.

3. Results and discussion

Fig. 1 shows the destabilizing effects of NiFe₂O₄ on LiBH₄ during non-isothermal desorption. Overall, a decrease in the onset dehydrogenation temperature and significant advance in desorption kinetics occur with the NiFe₂O₄ doping compared with the as-received LiBH₄. Especially, the LiBH₄ + 9 mol% NiFe₂O₄ sample has an outstanding reduction in the onset desorption temperature, approximately at 89 °C, which is 226 °C lower than the as-received LiBH₄. This shows an advance compared with previous literature reports.^{13,25} Moreover, it eventually liberates 10.75 wt% hydrogen, compared with merely 2.4 wt% for the as-received LiBH₄. Notably, 6.6 wt% hydrogen can be obtained below 250 °C, whereas there is no apparent

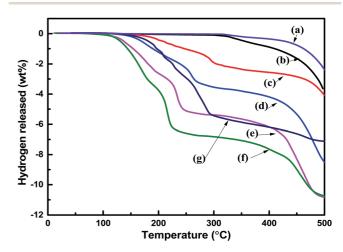

Fig. 1 Non-isothermal desorption curves of: (a) as-received LiBH₄, (b) as-milled LiBH₄ and as-milled LiBH₄ + (c) 3 mol%, (d) 5 mol%, (e) 7 mol%, (f) 9 mol%, and (g) 11 mol% NiFe₂O₄ nanoparticles.

hydrogen release until 300 °C in the pristine LiBH₄. It seems that the ball milling has less effect on improving the dehydrogenation performance of LiBH₄, as only 1.2 wt% more hydrogen liberated than the as-received LiBH4 and the initial release temperature is nearly unchanged. It can be seen from the other curves in Fig. 1 that the initial temperature falls to 136 °C, 116 °C and 88 °C for the LiBH₄ + 3, 5, 7 mol% NiFe₂O₄ samples, respectively. Similarly, the actual hydrogen storage capacity continues to grow, reaching 4.09, 8.52, and 10.84 wt%. On the other hand, there is one exception when the addition amounts up to 11 mol%, the destabilizing effect discussed above is less pronounced, with the onset temperature of 130 °C and 7.11 wt% of hydrogen. The rise of the initial dehydrogenation temperature and the loss of capacity may be because of excessive NiFe₂O₄ addition leading to the first dehydrogenation stage occurring during the ball milling process.

Considering kinetic properties and hydrogen capacity, the 9 mol% $NiFe_2O_4$ addition sample is used to analyze the destabilization effect of $NiFe_2O_4$ in the following tests.

Parallel to the non-isothermal analysis, the desorption kinetics at constant temperature and dynamic vacuum are also explored. The desorption characterization of the as-milled LiBH $_4$ is performed under the same conditions for comparison. As indicated in Fig. 2, owing to the sluggish kinetics of LiBH $_4$, the as-received LiBH $_4$ can only release 1.46 wt% hydrogen in the first 60 seconds at 300 °C and after 12 minutes the final desorbed hydrogen is merely 1.69 wt%. It is notable that after doping with 9 mol% NiFe $_2$ O $_4$, the content of desorbed hydrogen can increase to 2.74 wt% and the ultimate hydrogen obtained is 5.49 wt% within 20 minutes. To further review this prominent effect, the temperature is lowered to 200 °C. Within 12 minutes, dehydrogenation capacity of 2.48 wt% is achieved for the LiBH $_4$ + 9 mol% NiFe $_2$ O $_4$ sample. These results

Paper RSC Ad

demonstrate the NiFe $_2$ O $_4$ superiority in enhancing the LiBH $_4$ dehydrogenation kinetics compared with previous literature reports. 26,27 .

The difference of the hydrogen capacity at the same temperature in the isothermal and non-isothermal hydrogen dehydrogenation should be ascribed to the hydrogen pressure during desorption process, as the isothermal desorption is conducted in the dynamic vacuum and the non-isothermal at hydrogen pressure of 0.001 MPa. In other words, the external hydrogen pressure may influence hydrogen liberation. Both the non-isothermal and isothermal desorption results suggest that NiFe₂O₄ can significantly improve the dehydrogenation performance of LiBH₄.

To reveal the reaction mechanism in the desorption process, simultaneous differential scanning calorimetry and mass spectrometry (DSC-MS) measurements are carried out (Fig. 3). In the case of pristine LiBH4, there are three distinct endothermic signals at 114 °C, 285 °C and 428 °C, corresponding to orthorhombic to hexagonal structure transformation, fusion and decomposition of LiBH4, respectively. MS results show that a small amount of hydrogen is released at 285 °C and a rapid dehydrogenation is observed at 428 $^{\circ}\text{C},$ which is in agreement with the literature data. 26,29,30 Although there was report31 showing that downsizing may have dramatic effects on thermodynamic and kinetic properties of metal hydrides, the DSC-MS profile of as-milled LiBH₄ in this study is nearly the same as the pristine LiBH₄. It is speculated that this is because of the LiBH₄ size, which could not be decreased to the nano scale by ball milling. The slight influence of ball milling on accelerating the dehydrogenation properties of metal borohydride has also been reported in Li's study.32

It is notable that all three endothermic events in the case of LiBH₄ + 9 mol% NiFe₂O₄ have been shifted to lower temperature compared with commercial and milled LiBH4. The first endothermic peak at 102 °C is related to the orthorhombic to hexagonal structure transformation. The second one, accompanied by the major liberation of hydrogen in the MS profile, is associated with the interaction between LiBH₄ and NiFe₂O₄. The stronger and narrower hydrogen peak in the synchronous mass spectroscopy (MS) profile points to a rapid reaction. Considering the inferior amount of hydrogen and the melting temperature of commercial and as-milled LiBH4, the bump after the second peak at 253 °C is assigned to the residual LiBH₄ fusion. The DSC-MS results are in good agreement with the nonisothermal measurements. Other gases emitted besides hydrogen are depicted in Fig. 4. Inset figures are magnified data for BH3 and B2H6. Comparing emitted hydrogen, neither appreciable amounts of BH3 or B2H6 are detected by MS during the heating process. This is encouraging, since it usually poisons the fuel cells33,34 and is one of the reasons for the LiBH4 cycling capacity loss.35,36

From the results discussed above, it can be seen that the decomposition behavior of LiBH₄ + 9 mol% NiFe₂O₄ is different from commercial LiBH₄. Herein, it is imperative to ascertain the reaction mechanism. The XRD analysis is used to analyze the phase transition after ball milling and dehydrogenation. XRD patterns of the samples after ball milling are shown in Fig. 5, along with commercial LiBH₄ for comparison. For commercial LiBH₄, there are no other peaks found, except those belonging to LiBH₄. As for the as-milled LiBH₄, the peaks of LiBH₄ are relatively broadened due to the reduction in particle size. There are no visible diffraction peaks of LiBH₄ in the pattern of as-

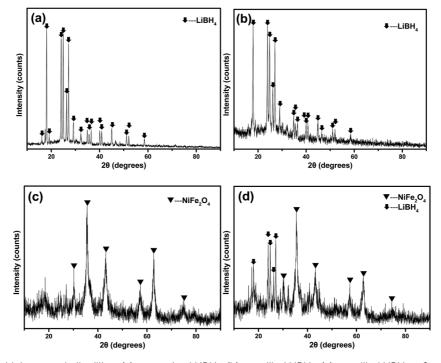

Fig. 5 XRD patterns after high energy ball milling: (a) as-received LiBH₄, (b) as-milled LiBH₄, (c) as-milled LiBH₄ + 9 mol% NiFe₂O₄ (d) as-milled LiBH₄ + 3 mol% NiFe₂O₄.

milled LiBH $_4$ + 9 mol% NiFe $_2$ O $_4$. To identify whether this is ascribed to the NiFe $_2$ O $_4$ addition, XRD study of LiBH $_4$ + 3 mol% NiFe $_2$ O $_4$ is conducted, as shown in Fig. 5(d). Although the diffraction peaks of LiBH $_4$ are visible in LiBH $_4$ + 3 mol% NiFe $_2$ O $_4$, their intensity is weaker than the as-milled LiBH $_4$. This means that the incremental content of NiFe $_2$ O $_4$ causes gradual decrease in the intensity of LiBH $_4$ diffraction peaks and increases the degree of LiBH $_4$ amorphization. It seems that there is no detectable reaction between LiBH $_4$ and NiFe $_2$ O $_4$ during the milling process, since no other phases are identified except for LiBH $_4$ and NiFe $_2$ O $_4$.

Fig. 6 shows the XRD patterns of the samples after dehydrogenation. Interestingly, for the pure LiBH₄ after dehydrogenation, the LiBH₄ peaks are still observed. However, this is reasonable if sluggish LiBH₄ kinetics is considered, since only 2.4 wt% hydrogen is released when heated to 500 °C. In addition to LiBH₄, LiH and LiBO₂ are also detected, where LiH phases are produced from the decomposition of LiBH₄, while LiBO₂ phases come from the air contamination during measurements. In the

case of LiBH₄ + 9 mol% NiFe₂O₄ sample, there are new diffraction peaks of LiBO₃, NiB, Fe₃O₄, and Fe₃B phases, caused by the interaction between LiBH₄ and NiFe₂O₄ during the dehydrogenation process. As Shan *et al.*³⁷ mentioned, most transition metal catalysts needs electrons to occupy the 3d orbit, and B has only one electron in the 2p orbit, while Fe and Ni have 6 and 8 electrons in the 3d orbit. Therefore, it is more feasible for B to provide an electron to Fe and Ni, achieving a more stable state. Herein, it is speculated that the destabilization effect of NiFe₂O₄ comes from the synergetic effects of NiB, Fe₃O₄ and Fe₃B.

Because of the limitations of XRD technique to detect amorphous or low content phases, Fourier transform infrared spectroscopy (FT-IR) is adopted to further reveal the reaction mechanism during the milling and de/re-hydrogenation process, as depicted in Fig. 7(a) and (b). Meanwhile, some dashed lines are added in Fig. 7 in order to better compare the peaks.

As seen in Fig. 7(a), as-received LiBH₄ exhibits the characteristic peaks of B-H stretching at 2387 cm⁻¹, 2295 cm⁻¹ and

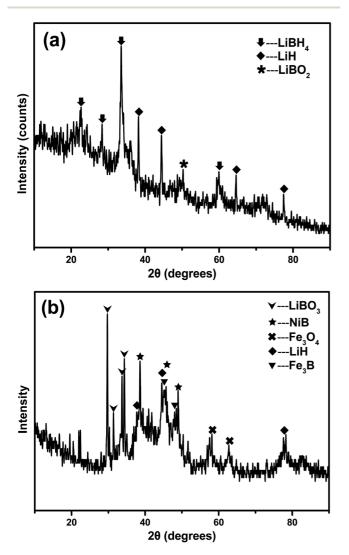

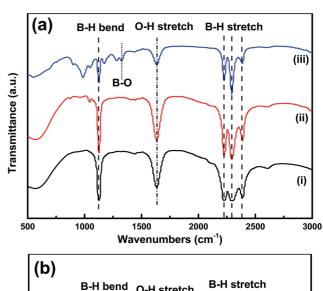

Fig. 6 XRD patterns of the samples after dehydrogenation: (a) as-received LiBH $_4$ and (b) as-milled LiBH $_4$ + 9 mol% NiFe $_2$ O $_4$.

Paper

2225 cm⁻¹, and B–H bending at 1126 cm⁻¹.^{21,26,30,38,39} The peak at 1633 cm⁻¹ corresponds to O–H stretches, which may be related to the moisture contamination during examinations^{13,14} and the hygroscopicity of KBr (even when dehydrated).^{25,27,40} The shape of the as-milled LiBH₄ spectrum is the same as the pristine one, indicating that LiBH₄ phases remain stable during the ball milling process.

As for the LiBH₄ sample milled with 9 mol% NiFe₂O₄, the characteristic B–H peaks remain, but with some new subtle peaks at 985 cm⁻¹, 1173 cm⁻¹, 1281 cm⁻¹ and 1325 cm⁻¹. The peak at 1281 cm⁻¹ is B–H,³⁰ which cannot be observed in the commercial LiBH₄, suggesting some other LiBH₄ phases. The peak at 1325 cm⁻¹ is assigned to the vibration modes of the B–O bonds,⁴¹ pointing to partial interaction between NiFe₂O₄ and LiBH₄ during the milling process.

With respect to the samples after dehydrogenation in Fig. 7(b), one can also find the same B–H peaks remaining in the case of as-received LiBH₄, compared to that before dehydrogenation, which further validates the XRD results. When it comes to the LiBH₄ + 9 mol% NiFe₂O₄ sample after dehydrogenation, it is found that all characteristic peaks of B–H stretching at 2387 cm⁻¹, 2295 cm⁻¹ and 2225 cm⁻¹ and B–H bending at 1126 cm⁻¹ disappear, suggesting that LiBH₄ is completely decomposed. The fresh peaks at 745 cm⁻¹ and 2455 cm⁻¹ are attributed to [B₁₂H₁₂]⁻¹, indicating LiBH₄ decomposition into Li₂B₁₂H₁₂.²⁸ The FT-IR results confirm that NiFe₂O₄ can facilitate the decomposition of LiBH₄. Additionally, there is a partial reaction between LiBH₄ and NiFe₂O₄ during the ball milling process and LiBH₄ is partially reversed after the addition of NiFe₂O₄.

For better understanding of the potential destabilization mechanism, field scanning electron microscopy (FESEM) observations are conducted. Fig. 8 depicts FESEM images of the as-received, as-milled LiBH $_4$ and as-milled LiBH $_4$ + 9 mol% NiFe $_2$ O $_4$. Prior to ball milling, the particle size of LiBH $_4$ ranges from 1 μ m to 5 μ m irregularly, posing a disadvantage to the dehydrogenation kinetics. For the commercial LiBH $_4$ after ball milling, the particles become much smaller, forming clusters, which also block rapid dehydrogenation. However, after ball milling with NiFe $_2$ O $_4$, as shown in Fig. 8(c), the particle size declines to 300 nm and 800 nm, and the distribution of these particles become more uniform. This may be one of reasons for the enhancement of dehydrogenation kinetics, as these nanosized particles may serve as the nucleation sites. One thing should be noted that the embedded NiFe $_2$ O $_4$ cannot be seen in the LiBH $_4$ matrix owing to its nano particle size.

From the above analysis, the superior destabilizing effects may result from the ball milling with NiFe₂O₄, leading to the significant LiBH₄ particle size decline.

Since the NiFe₂O₄ nanoparticles could not be observed by FESEM, it is imperative to observe the nanostructure of un-doped and doped sample to further demonstrate the superior effects of nano-sized NiFe2O4. Fig. 9 shows dark field images, HRTEM and EDX analyses in the as-milled LiBH₄ + 9 mol% NiFe₂O₄ sample. In Fig. 9(a) some black particles are homogenously distributed among the grey matrix. To figure out what these particles are, corresponding EDX measurements of the black area A and the grey area B are conducted, as shown in Fig. 9(c) and (d), respectively. For the black area, O, Fe, Ni and Cu elements are identified (Cu comes from the sample holder). Although Fe and Ni elements are detected in the grey area, their intensity is much weaker than in the black area. It must be pointed out that EDX cannot reliably detect LiBH4 due to the weak scattering of electrons by the light Li, B and H elements. Thus, it could be said that the black nanoparticles correspond to NiFe2O4, while the grey correspond

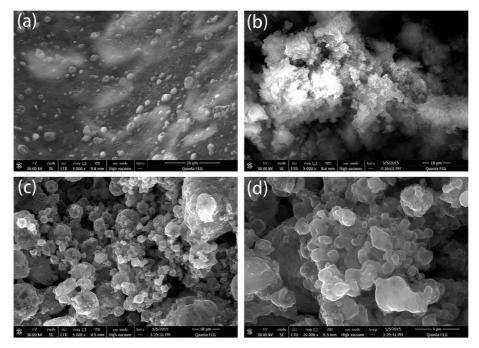

Fig. 8 FESEM images of (a) as-received LiBH₄ (b) as-milled LiBH₄ (c) as-milled LiBH₄ + 9 mol% NiFe₂O₄ and (d) is magnified image of (c).

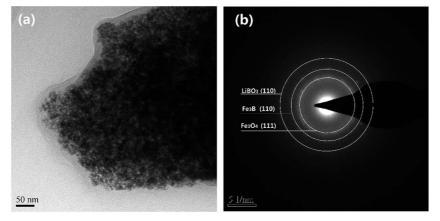

Fig. 10 (a) TEM micrograph and (b) corresponding SAED pattern of as-milled LiBH₄ + 9 mol% NiFe₂O₄ after dehydrogenation.

to ${\rm LiBH_4}$. It can be concluded that the ${\rm NiFe_2O_4}$ nanoparticles are homogenously embedded in the ${\rm LiBH_4}$ matrix after ball milling, improving rapid dehydrogenation kinetics.

LiBH₄ is detected by the FT-IR measurements, but not XRD, which was previously attributed to the amorphous state of LiBH₄ after ball milling with NiFe₂O₄. To demonstrate this, HRTEM images were obtained. As expected, there is some amorphization in the oval area, which is consistent with the FT-IR results and XRD analysis. The electron micrograph of dehydrogenated LiBH₄ + 9 mol% NiFe₂O₄ is shown in Fig. 10(a), which looks similar to the as-milled sample with some nanoparticles spread evenly among the grey areas. To further investigate the microstructure of LiBH₄ + 9 mol% NiFe₂O₄, selected

area electronic diffraction (SAED) results are shown in Fig. 10(b). The dim lattice diffraction pattern indicates that there is a high degree of amorphization, which can also be demonstrated by the broader XRD reflections. Additionally, the existence of Fe_3B and Fe_3O_4 phases are proven by the SAED measurements.

Conclusions

In this paper, it is found the nano-sized nickel ferrite (NiFe $_2$ O $_4$) can effectively destabilize LiBH $_4$. According to the non-isothermal and isothermal desorption results, it liberates hydrogen at 89 °C and the hydrogen capacity is 10.75 wt% and

Paper RSC Advances

one could get 5.49 wt% in just 20 minutes. In comparison with the raw LiBH₄, this is a huge advance. The mass spectroscopy detect neither BH₃ nor B₂H₆, which poison the fuel cells and can often lead to H₂ capacity loss, other than pure hydrogen. The XRD patterns combined with the SAED measurements uncover the existence of the Fe₃B, NiB and Fe₃O₄, which show a synergetic effect on accelerating the dehydrogenation properties of LiBH₄. The FT-IR results reveal that the addition of NiFe₂O₄ leads to the complete decomposition of LiBH₄ when heated to 500 °C, while there is still a big surplus of LiBH₄ for the undoped one. The FESEM figures indicate that the particle size of LiBH₄ declines significantly after ball milling with NiFe₂O₄.
